Abstract. The bainitic reaction in steels has been extensively studied, however it is still controversial whether it proceeds by a diffusional or a shear mechanism. In a previous investigation of the bainite reaction in a Fe-3.9Si-0.9C steel the transformation was considered to be the result of two competing elementary mechanisms, i.e., the shear transformation of the γ -iron lattice and the diffusion of interstitial carbon away from the transformation interface. According to this model, the transition from upper to lower bainite occurs when the rate of interstitial carbon traversing the γ/α interface becomes of the same order with the velocity of the shear front. This interpretation stipulates that the carbon content corresponding to the γ/α and T_0 curves of austenite is critical. Using step quench experiments and determining the percentage of the residual austenite and its carbon content it was demonstrated that both $X_{\gamma/\alpha}$ and X_{T_0} contents of austenite play an important role in the initiation of its decomposition and its incomplete transformation. In this paper, the microstructural and crystallographic characteristics of the bainite products obtained through the step quenching experiments are examined, using TEM and Electron diffraction. The results are compared to those obtained by the corresponding bainitic transformation in a single step. The obtained results clearly corroborate the aforementioned model of transformation, which necessitates both a shear mechanism of the iron lattice and a redistribution of carbon between the parent phase and its transformation products.

1. INTRODUCTION

The bainitic reaction in steels has been extensively studied, however it is still controversial whether it proceeds by a diffusional or a shear mechanism [1-3].

In a previous investigation of the bainite reaction in a Fe-3.9Si-0.9C steel the transformation was considered to be the result of two competing elementary mechanisms, i.e., the shear transformation of the α -iron lattice and the diffusion of interstitial carbon away from the transformation interface. According to this model, the transition from upper to lower bainite occurs when the rate of interstitial carbon traversing the γ/α interface becomes of the same order with the velocity of the shear front. Using step quench experiments and determining the percentage of the residual austenite and its carbon content it was demonstrated that both $X_{\gamma/\alpha}$ and X_{T_0} contents of austenite play an important role in the initiation of its decomposition and its incomplete transformation [4].

In this paper, the microstructural and crystallographic characteristics of the bainite products obtained through the step quenching experiments are examined, using TEM and Electron diffraction. The results are compared to those obtained by the corresponding bainitic transformation in a single step. The results obtained here support the proposed model in [4] and the shear character of the bainitic transformation [7].

2. EXPERIMENTAL

The same steel as in [4], an alloy with 3.9 w.t.% silicon and 0.9 w.t.% carbon, was used. After austenitizing at 1130°C for 30 minutes a number of samples were transformed at 420°C for 30 minutes and then quenched in a second bath where they were kept for times increasing from one to thirty days at temperatures of either 360, 340 or 290°C. The microstructure of the samples was examined using TEM and Electron Diffraction.

3. RESULTS AND DISCUSSION

When the bainite reaction in the Si- alloyed steel under consideration is initiated at 420°C, it soon reaches a transformation "stasis" after a period of 30 minutes, corresponding to 51 at.% decomposition of austenite. The microstructure and the kinetics of the primary stage have been discussed elsewhere [5-6]. The product consists of a mixture of bainitic ferrite in the form of needles composed of smaller sub-units and residual austenite, enriched up to a content of 1.83 w.t.% carbon [4]. No carbides are precipitated, unless the reaction is prolonged for several days. The orientation relationship between ferrite and austenite is very close to that of Nishiyama-Wassermann, i.e. : $(011)_b // (111)_f$, $[\bar{0}\bar{1}]_b // [\bar{1}\bar{1}2]_f$ and $[100]_b // [\bar{1}10]_f$ [6].

When the partially transformed samples are isothermally treated to a lower reaction temperature of either 360 or 340°C no change in the previous microstructure obtained at 420°C is observed, apart from a slight increase in the carbon content of the enriched austenite.

However, when the second reaction temperature is set as low as 290°C, further decomposition of austenite occurs, producing a second generation of bainitic ferrite. The residual austenite is 36 at.% and is further enriched to 2.03 w.t.% carbon.

The micrograph of Figure 1 shows that apart from the well known massive ferrite needles of the first generation formed at 420°C (marked α_1), a second generation of ferrite (marked α_2) is easily distinguished. This second generation of ferrite, shown better in Fig.2, is much finer. Figures 3 and 4 are the dark field images of the second generation of ferrite and austenite respectively shown in Fig.2. The corresponding selected area diffraction pattern is shown in Figure 5. It is confirmed that the orientation relationship between the austenite and the second generation of ferrite is close to the Kurdjumov-Sachs relationship, i.e.

$$(011)_b // (\bar{1}\bar{1}\bar{1})_f, [111]_b // [10\bar{1}]_f \text{ and } [2\bar{1}1]_b // [\bar{1}21]_f.$$

Figs. 6 and 7 allow a direct comparison of the microstructural characteristics of bainite formed at 420 and 290°C. The needles formed at 420°C have a total width of about 1 to 2 μm , while the needles formed at 290°C have a total width of only 0.05 to 0.3 μm . However in both of them needles appear as packets of smaller sub-units. The subunits formed at 290°C are finer and more elongated and in some cases do not appear to form packets but they are rather isolated.

The austenite surrounding the ferrite needles formed at 420°C has a high density of dislocations, which is higher near the austenite/ferrite interface (Fig.6). The austenite entrapped between the needles of the second generation ferrite formed at 290°C contains, apart from clusters of dislocations associated to the γ/α interface, extensive faulting. Fig. 8 is the bright field image of austenite in contact with a second generation ferrite needle. The corresponding diffraction pattern of Fig.9 shows that the defects are twins with a $(111)_f$ twinning plane. Figure 10 is a dark image field taken on a (020) -twin reflection of austenite.

The fact that the austenite twins occur systematically in contact with the second generation of ferrite, while they are only exceptionally present near the first generation of ferrite or in samples reacted only at 420°C, shows that they are associated to the formation of the second generation of ferrite. This implies that the austenite is highly stressed during the transformation at 290°C. The formation of twins should be connected to the shape strain accompanying the formation of ferrite, i.e. the shear character of the transformation, combined to the difficulty of stress relaxation at this low temperature. Another important factor may be the lower diffusivity of carbon causing the ferrite to stay for a longer time in supersaturation. This is in agreement with the hypothesis done in [4] that at temperatures below 300-310°C the diffusion of carbon away of the forming ferrite subunit is slower than the rate of shear of the iron lattice.

These results corroborate clearly the aforementioned model of the bainitic transformation [4], which necessitates both a shear mechanism of the iron lattice and a redistribution of carbon between the parent phase and its transformation products. Furthermore it is interesting to note that no second generation of ferrite was observed when the second isothermal treatment was done at 360 (or at 340°C), although at these temperatures a slight enrichment of austenite beyond its original value of 1.83 w.t.% carbon was observed. This is in agreement with the hypothesis that at the end of the primary stage at 420°C the carbon content of austenite (1.83 w.t.% carbon) is between the x_{T_0} and $x_{\gamma/\alpha}$ at the temperatures of the second isothermal treatment, and consequently the transformation by shear is impossible, although some diffusional growth of the ferrite needles leading to a slight enrichment of austenite is possible. In contrast, a second generation of bainitic ferrite forms at 290°C, where apparently, the original carbon content of austenite (1.83 w.t.% carbon) is lower than the x_{T_0} value at 290°C. Indeed, the ferrite formed at 290°C is really a bainite and has its main microstructural characteristics in common with the bainite formed at 420°C.

These observations show that the carbon content of austenite, compared to the x_{T_0} and $x_{\gamma/\alpha}$ values at the temperature of the transformation are crucial for the bainitic transformation, as it is explained in [4].
